1. Problem Description

This project was carried out within the scope of the CPD discipline, of the Computer Engineering course at FEUP. Its goal was the study of the effect of memory hierarchy and of different access patterns to an array on processor performance when accessing large amounts of data. To this end, we applied different algorithms to calculate the product of two matrices, also making use of the performance API (PAPI) to collect relevant performance indicators from the program execution.

2. Explanation of the Algorithms

We started by implementing three sequential algorithms. The first one is the **normal multiplication** algorithm where the result is obtained by multiplying one line of the first matrix by each column of the second matrix, which is the most common method for multiplying two matrices. To the second implementation we call the **line multiplication** algorithm because it starts by multiplying each element of the first matrix by the corresponding row in the second matrix, before moving on to the next element. The last one is the **block multiplication**, where we start by dividing the matrices into smaller ones with a specific size, and then, for each one of them, we run the same algorithm as used in the line multiplication.

We also made alterations to the line multiplication algorithm so that we could make use of parallel computation. The **first version** parallelizes the outermost loop (loop over 'i'), so each thread works on a separate chunk of the outer loop iterations with size n/p where n is the matrix size and p is the number of threads (in our case, 8), which means that each thread executes a subset of iterations of 'i', where for each 'i', the inner loops ('k' and 'j') are executed sequentially within each thread. The **second version** parallelizes the innermost loop (loop over 'j'). This means that all iterations of the 'i' and 'k' loops will be executed by all threads in the parallel region, but the 'j' loop iterations will be distributed among the threads.

3. Performance Metrics

Through the use of the performance API (PAPI), we were able to store the number of cache misses to the L1 and L2 cache. In addition, we also recorded the execution time for each matrix size and algorithm, which also allowed us to calculate the FLOPS.

In the cases where parallel computing was used, we also calculated the speedup and efficiency for each case.

4. Results and Analysis

For each algorithm and matrix' size, we run the code ten times. Due to this, the results presented in the attachments come from the calculation of the average time and the average values of L1 Data Cache Misses and L2 Data Cache Misses. The GFlops were calculated using the average time.

4.1. Differences in Normal and Line Multiplication's Algorithms

The Normal Multiplication algorithm grows exponentially as the size of the matrices increases. However, it is possible to see that the Line Multiplication algorithm grows in a much more constant way, where it is possible to notice a greater difference between the results in C++ and Java. We registered 10 values for each case and we noticed that the first times obtained in Java, for each matrix size, were considerably smaller than the following ones. For example, in the case of the 3000x3000 matrix, the first result obtained was 17,115 seconds, but the following results were substantially higher, with the average being 25,528 seconds.

The Line Multiplication algorithm is much faster and more efficient than the Normal Multiplication algorithm, being even more noticeable as the size of the matrix increases. This difference happens due to the way the cache is accessed throughout the process, and we can see the differences between the number of misses in the L1 and L2 caches.

First of all, it is important to keep in mind that whenever a value is needed, a copy is made to the cache of an entire block of memory that contains that value.

In the Normal Multiplication algorithm, it starts in the first loop by accessing a block of memory containing the row of the first matrix that will be multiplied, but then it will fetch the first element of each column of the second matrix. This method becomes inefficient as the elements of the matrix that are in the same column may be very far from each other in memory (number of columns), meaning that they may not be found in the block copied to the cache. However, in the Line Multiplication algorithm, since it is row by row, the problem that occurred before when doing it by columns does not occur. Since blocks of memory with continuous values are copied, they will correspond to a line, or part of it, that is, they can already be in the cache when they are needed.

We can also observe that the number of cache misses in the normal algorithm increases exponentially with the increase in matrix dimensions, as the memory distance of the values used increases. This results in a lower probability of these values already being in the lower levels of memory, making it necessary to access higher levels more frequently to

fetch the data, and, consequently, for the same number of operations, a lower value of FLOPS.

4.2. Differences in Block Multiplication's Algorithm

As we can see from the graph below, this algorithm is more efficient than the previous ones. This is due to the fact that we divide the same problem into several smaller ones, that is, we divide a very large matrix into several smaller ones. By dividing the matrix into smaller blocks we increase the temporal coherence of each value since the time between accesses to the same position is reduced.

We also noticed that bigger blocks tend to perform better, though in the case of matrices of 8192 x 8192 the runs with block size 128 were substantially faster than with larger blocks.

4.3. Differences in Parallel Implementations

When using parallel computing, we can verify that there is a temporal improvement in the results obtained compared to those previously obtained when doing sequentially since we are using more of the processor's capabilities by leveraging multiple cores at the same time.

We started by making the first version, with the outermost loop run in parallel, which was the case where we saw better results, having a speedup between 3,5 and 7, but we also found that as we used larger matrices, efficiency decreased because the problem became more bound by the memory speed. In the second version, only the innermost loop was executed in parallel, which led to a speedup between 0,5 and 1,5, and an increase in execution time compared to the previous one, but unlike that one, its efficiency improved with an increase in matrix size.

A difference in results between the two implementations can be attributed to how parallelization is carried out. When we parallelize the outermost loop, its iterations are divided among the threads, and each thread executes a continuous block of iterations. Upon completion of these iterations, synchronization occurs between the threads. On the other hand, when we parallelize the innermost loop, all threads execute all iterations of the outer loops, while only the iterations of the inner loop are divided among them. This results in the need for synchronization between the threads after each execution of the inner loop, which can affect performance due to additional synchronization overhead.

5. Conclusion

This project was a great opportunity to verify that different implementations that perform the same kind of task can have different performances and how part of that is due to the way we access the memory.

We found that the way our program interacts with the cache can have a big impact on performance, and that to take advantage of it we must perform memory access sequentially and keep each access to the same region of memory close in time.

We also found that using parallel processing when available can also have a considerable impact on the speed of the program.
